

# Chapter 2

## Training Machine Learning Algorithms for Classification

August 14, 2017

# Logic Gate

- Simple logic gate with binary outputs
- Signals arrive at dendrites
- Integrated into cell body
- If signal exceeds threshold, generate output, and pass to axon

# Rosenblatt Perceptron

- Binary classification task
- Positive class (1) vs. negative class (-1)
- Define activation function  $\phi(z)$
- Takes as input a dot product of input and weights
- Net input:  $z = w_1x_1 + \dots + w_mx_m$

$$\mathbf{w} = \begin{bmatrix} w^{(1)} \\ w^{(2)} \\ \vdots \\ w^{(m)} \end{bmatrix}, \mathbf{x} = \begin{bmatrix} x^{(1)} \\ x^{(2)} \\ \vdots \\ x^{(m)} \end{bmatrix}$$

# Heaviside step function

- $\phi(z)$  known as activation
- if activation above some threshold, predict class 1
- predict class -1 otherwise

Heaviside Step Function

$$\phi(z) = \begin{cases} 1 & \text{if } z \geq \theta \\ -1 & \text{otherwise .} \end{cases}$$

# Step function simplified

Bring the threshold  $\theta$  to the left side of the equation and define a weight-zero as  $w_0 = -\theta$  and  $x_0 = 1$ , so that we write  $\mathbf{z}$  in a more compact form

$$z = w_0x_0 + w_1x_1 + \cdots + w_mx_m = \mathbf{w}^T \mathbf{x}$$

and

$$\phi(z) = \begin{cases} 1 & \text{if } z \geq 0 \\ -1 & \text{otherwise .} \end{cases}$$

Vector dot product

$$z = \mathbf{w}^T \mathbf{x} = \sum_{j=0}^m w_j x_j$$

$$\begin{bmatrix} 1 & 2 & 3 \end{bmatrix} \times \begin{bmatrix} 4 \\ 5 \\ 6 \end{bmatrix} = 1 \times 4 + 2 \times 5 + 3 \times 6 = 32.$$

# Input squashed into a binary output

# Rosenblatt perceptron algorithm

- ① Initialize the weights to 0 or small random numbers.
- ② For each training sample  $\mathbf{x}^{(i)}$ , perform the following steps:
  - ① Compute the output value  $\hat{y}$ .
  - ② Update the weights.

# Weight update

Weight update rule:

$$w_j := w_j + \Delta w_j$$

Perceptron learning rule:

$$\Delta w_j = \eta \left( y^{(i)} - \hat{y}^{(i)} \right) x_j^{(i)}$$

Where  $\eta$  is the learning rate (a constant between 0.0 and 1.0),  $y^{(i)}$  is the true class label of the  $i$ th training sample, and  $\hat{y}^{(i)}$  is the predicted class label.

# Update rule examples

Correct prediction, weights unchanged:

$$\Delta w_j = \eta \left( -1 - -1 \right) x_j^{(i)} = 0$$

$$\Delta w_j = \eta \left( 1 - 1 \right) x_j^{(i)} = 0$$

Wrong prediction, weights pushed towards the positive or negative class:

$$\Delta w_j = \eta \left( 1 - -1 \right) x_j^{(i)} = \eta(2)x_j^{(i)}$$

$$\Delta w_j = \eta \left( -1 - 1 \right) x_j^{(i)} = \eta(-2)x_j^{(i)}$$

# Linear separability

Convergence guaranteed if

- The two classes linearly separable
- Learning rate is sufficiently small

If classes cannot be separated:

- Set a maximum number of passes over the training dataset (epochs)
- Set a threshold for the number of tolerated misclassifications
- Otherwise, it will never stop updating weights (converge)

# Linear separability

# Perceptron implementation

► [iPython notebook on github](#)

# ADAPtive LInear NEuron (Adaline)

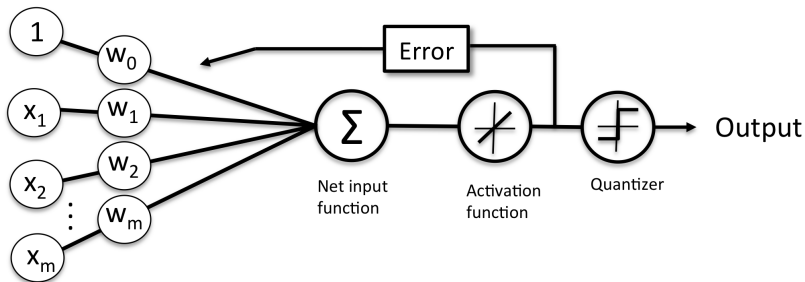

- Weights updated based on a linear activation function
- Remember that perceptron used a unit step function
- $\phi(z)$  is simply the identity function of the net input

$$\phi(\mathbf{w}^T \mathbf{x}) = \mathbf{w}^T \mathbf{x}$$

- A quantizer is then used to predict class label

# Adaline: notice the difference with perceptron

# Cost functions

- ML algorithms often define an *objective* function
- This function is optimized during learning
- It is often a *cost* function we want to minimize
- Adaline uses a cost function  $J(\cdot)$
- Learns weights as the sum of squared errors (SSE)

$$J(\mathbf{w}) = \frac{1}{2} \sum_i \left( y^{(i)} - \phi(z^{(i)}) \right)^2$$

# Advantages of Adaline cost function

- The linear activation function is differentiable
- Unlike the unit step function
- It is convex
- Can use *gradient descent* to learn the weights

# Gradient Descent

- Weights updated by taking small steps
- Step size determined by learning rate
- Take a step away from the gradient  $\nabla J(\mathbf{w})$  of the cost function

$$\mathbf{w} := \mathbf{w} + \Delta \mathbf{w}.$$

- The weight change is defined as follows:

$$\Delta \mathbf{w} = -\eta \nabla J(\mathbf{w})$$

# Gradient computation

To compute the gradient of the cost function, we need to compute the partial derivative of the cost function with respect to each weight  $w_j$ ,

$$\frac{\partial J}{\partial w_j} = - \sum_i \left( y^{(i)} - \phi(z^{(i)}) \right) x_j^{(i)},$$

Weight update of weight  $w_j$

$$\Delta w_j = -\eta \frac{\partial J}{\partial w_j} = \eta \sum_i \left( y^{(i)} - \phi(z^{(i)}) \right) x_j^{(i)}$$

We update all weights simultaneously, so Adaline learning rule becomes

$$\mathbf{w} := \mathbf{w} + \Delta \mathbf{w}.$$

$$\begin{aligned}\frac{\partial J}{\partial w_j} &= \frac{\partial}{\partial w_j} \frac{1}{2} \sum_i \left( y^{(i)} - \phi(z^{(i)}) \right)^2 \\&= \frac{1}{2} \frac{\partial}{\partial w_j} \sum_i \left( y^{(i)} - \phi(z^{(i)}) \right)^2 \\&= \frac{1}{2} \sum_i 2(y^{(i)} - \phi(z^{(i)})) \frac{\partial}{\partial w_j} (y^{(i)} - \phi(z^{(i)})) \\&= \sum_i (y^{(i)} - \phi(z^{(i)})) \frac{\partial}{\partial w_j} \left( y^{(i)} - \sum_i (w_j^{(i)} x_j^{(i)}) \right) \\&= \sum_i \left( y^{(i)} - \phi(z^{(i)}) \right) \left( -x_j^{(i)} \right) \\&= - \sum_i \left( y^{(i)} - \phi(z^{(i)}) \right) x_j^{(i)}\end{aligned}$$

# Adaline learning rule vs. Perceptron rule

- Looks identical
- $\phi(z^{(i)})$  with  $z^{(i)} = \mathbf{w}^T \mathbf{x}^{(i)}$  is a real number
- And not an integer class label as in Perceptron
- The weight update is done based on *all* samples in training set
- Perceptron updates weights incrementally after each sample
- This approach is known as “batch” gradient descent

# Perceptron implementation

► [iPython notebook on github](#)

# Lessons learned

- Learning rate too high: error becomes larger (overshoots global min)
- Learning rate too low: takes many epochs to converge
- Feature normalization

# Stochastic gradient descent (SGD)

- Large dataset with millions of data points (“big data”)
- Batch gradient descent costly
- Need to compute the error for the entire dataset ...
- ... to take one step towards the global minimum!

$$\Delta \mathbf{w} = \eta \sum_i \left( y^{(i)} - \phi(z^{(i)}) \right) \mathbf{x}^{(i)}.$$

- SGD updates the weights incrementally for each training sample

$$\Delta \mathbf{w} = \eta \left( y^{(i)} - \phi(z^{(i)}) \right) \mathbf{x}^{(i)}.$$

- Approximation of gradient descent
- Reaches convergence faster because of frequent weight updates
- Important to present data in random order
- Learning rate often gradually decreased (adaptive learning rate)
- Can be used for online learning
- Middle ground between SGD and batch GD is known as *mini-batch learning*
  - E.g. 50 examples at a time
  - Can use vector/matrix operations rather than loops as in SGD
  - Vectorized operations highly efficient
